Attorney's Docket No.: CIT98-01pA2

ARTERY- AND VEIN-SPECIFIC PROTEINS AND USES THEREFOR

RELATED APPLICATIONS

This application is a continuation-in-part of U.S. Application Number 09/1783,546, (Attorney Docket Number CIT98-01pA1) entitled Artery- and Vein-Specific Proteins and Uses Therefor, by Hai U. Wang, Zhoufeng Chen and David J. Anderson, filed on May 22, 1998. This application also claims the benefit of U.S. Provisional Application Number 60/108177, 1, entitled Molecular Distinction and Angiogenic 1.

10 Interaction Between Embryonic Arteries and Veins Revealed by EphrinB2 and its Receptor EphB4, by Hai U. Wang and David J. Anderson, filed on April 13, 1998. The teachings of both of these applications are incorporated herein by reference in their entirety.

15 FUNDING

The invention was supported, in whole or in part, by the Howard Hughes Medical Institute

BACKGROUND OF THE INVENTION

20 The process of blood vessel formation is fundamental in both development and disease. The circulatory system is the first organ system to emerge during embryogenesis, and is necessary to nourish the developing fetus. Disorders of the

circulatory system, such as coronary artery disease, are a major cause of morbidity and mortality in modern society. Thus, repairing, replacing and promoting the growth of blood vessels is a major target of clinical research and of 5 pharmaceutical development. Conversely, the ingrowth of new capillary networks into developing tumors is essential for the progression of cancer. Thus, the development of drugs that inhibit this process of tumor angiogenesis is an equally important therapeutic goal. Little attention has 10 been paid to the problem of how arteries and veins acquire their distinct identities. Indeed, many people have assumed that the anatomical and functional differences between arteries and veins simply reflect physiological influences, such as blood pressure, oxygenation and shear forces. 15 Additional knowledge of how arteries and veins acquire their respective identities would be valuable in both research and clinical settings.

SUMMARY OF THE INVENTION

20 The present invention relates to a method of distinguishing between arterial endothelial cells and venous endothelial cells based on the expression of a protein on one type of such endothelial cells (e.g., on arterial endothelial cells) and not on the other (e.g., not on venous 25 endothelial cells) and to a wide variety of processes, methods and compositions of matter, including those useful in research and clinical settings, which are based on the difference in expression between the two cells types. As described herein, it has been shown that there is a 30 molecular distinction between arterial endothelial cells (arteries) and venous endothelial cells (veins) and that arterial endothelial cells and venous endothelial cells bear molecular markers which can be used to identify, separate, target, manipulate or otherwise process each cell type

specifically (separate from the other). As a result, arteries and veins can now be distinguished from one another, assessed for other genetic molecular or functional differences and targeted, manipulated or otherwise processed 5 individually or separately for research, diagnostic and therapeutic purposes.

The present invention relates to methods of distinguishing or separating arterial endothelial cells (arteries) from venous endothelial cells (veins) based on 10 their respective molecular markers; methods of selectively targeting or delivering drugs or agents to arteries or veins; methods of altering (enhancing or inhibiting, where "inhibiting" includes partially or completely inhibiting) the function of artery-specific or vein-specific molecular 15 markers or interaction between them (and, thus, enhancing or inhibiting the effect such functions or interactions have on arterial endothelial cells or venous endothelial cells); and methods of screening for drugs which act selectively on arterial endothelial cells or venous endothelial cells. The 20 invention also relates to transgenic nonhuman mammals, such as transgenic mice, in which genes encoding an arterial endothelial cell molecular marker or a venous endothelial cell molecular marker are altered, either physically or functionally, and their use as "indicator mice" to 25 specifically visualize either arteries or veins, to assess the function of the molecular marker which has been altered and to identify drugs which affect (enhance or inhibit) their function. It further relates to antibodies which bind an arterial endothelial cell-specific marker or a venous 30 endothelial cell-specific marker; viral or other vectors targeted to arteries or veins by virtue of their containing and expressing, respectively, an arterial endothelial cell-specific marker or a venous endothelial cell-specific marker; cDNAs useful for preparing libraries to be screened

for additional artery- or vein- specific genes and immortalized cell lines derived from isolated arterial endothelial cells or venous endothelial cells or from transgenic animals (e.g., mice) of the present invention.

5 A molecular marker for an arterial endothelial cell or a venous endothelial cell is any gene product (protein or RNA or combination thereof) expressed by one of these cell types and not on the other. Such markers are also referred to, respectively, to as arterial endothelial cell-specific (artery-specific) and venous endothelial cell-specific (vein-specific) products or proteins. In specific 10 embodiments, they are referred to, respectively, as arterial endothelial cell-specific (artery-specific) ligands and venous endothelial cell-specific (vein-specific receptors..

15 Such molecular markers can be expressed on cell types in addition to arterial or venous endothelial cells, but are not expressed on both arterial and venous endothelial cells. Molecular markers can include, for example, mRNAs, members 20 of ligand-receptor pairs, and any other proteins such as adhesion proteins, transcription factors or antigens which are not expressed on both cell types. In one embodiment, the molecular marker is a membrane receptor which is the receptor for a growth factor which acts on arteries or veins (e.g., fibroblast growth factor-2 (FGF), vascular 25 endothelial growth factors (VEGF 1-3, angiopoietins). In another embodiment the molecular marker is a member of an endothelial cell surface ligand-receptor pair which is expressed on arterial or venous endothelial cells, but not on both. For example, as described in detail herein, a 30 member of the Ephrin family of ligands and a member of the Eph family of receptors which is its receptor are molecular markers for arterial endothelial cells and venous endothelial cells, respectively and are useful to distinguish the two cell types. Any Ephrin family ligand

which is expressed on arterial endothelial cells, but not on venous endothelial cells and a venous endothelial cell-specific Eph family receptor which binds the arterial endothelial cell-specific ligand can be used to distinguish 5 between arteries and veins.

In one embodiment, the present invention relates to the discovery that arterial endothelial cells express an Ephrin family ligand and venous endothelial cells express an Eph family receptor which is a receptor of the Ephrin family ligand expressed on the arterial endothelial cells; methods of distinguishing or separating arterial endothelial cells (arteries) from venous endothelial cells (veins); methods of selectively targeting or delivering drugs or agents to arteries or veins; methods of enhancing or inhibiting angiogenesis, such as by altering (increasing, decreasing or prolonging) activity of at least one member of an Ephrin family ligand-cognate Eph family receptor pair and drugs useful in the methods; and methods of screening for drugs which selectively act on arterial endothelial cells or venous endothelial cells. It further relates to transgenic nonhuman mammals, such as transgenic mice, which have altered genes encoding an Ephrin family ligand or altered genes encoding an Eph family receptor, such as EphrinB2 knockout mice which contain a *tau-lacZ* (*tlacZ*) insertion that marks arteries but not veins or EphB4 knockout mice which contain a reporter construct (e.g., *lacZ* or alkaline phosphatase gene) in the EphB4 locus; methods of using these mice as "indicator mice" to define and visualize angiogenic processes (e.g., tumor angiogenesis and ischemia-associated cardiac neovascularization) or to screen drugs for their angiogenic or anti-angiogenic effects on arteries or veins *in vivo*; and cells, such as immortalized cells, derived from the transgenic mice. The present invention also relates to antibodies which bind an artery-specific Ephrin family

卷之三

receptor (e.g., antibodies which bind EphrinB2); antibodies which bind a venous-specific Eph family receptor (e.g., antibodies which bind EphB4); viral or other vectors which are targeted to arteries or veins for vessel-specific gene

5 therapy by virtue of their containing and expressing DNA encoding, respectively, an Ephrin family ligand (e.g., EphrinB2) or an Eph family receptor (e.g., EphB4); cDNAs useful for preparing libraries to be screened for additional artery-specific or vein-specific genes (whose gene products,

10 in turn, might be artery-or vein-specific drug targets) and methods of repairing or replacing damaged arteries or veins by transplantation of isolated arterial or venous endothelial cells, immortalized cell lines derived from them or synthetic vessels configured from these cells.

15 As described herein and as is known to those of skill in the art, Ephrin family ligands are divided into two subclasses (EphrinA and EphrinB) and Eph family receptors are divided into two groups (EphA and EphB). As is also known, within each subclass or group, individual members are

20 designated by an arabic number. The invention is described herein with specific reference to EphrinB2 and EphB4. However, other Ephrin family ligand-Eph family receptor pairs which show similar artery-and vein-specific expression and their uses are also the subject of this invention.

25 Similar artery- and vein-specific pairs can be identified by methods known to those of skill in the art.

BRIEF DESCRIPTION OF THE DRAWINGS

Figure 1A is a diagram of the wild type locus of the EphrinB2 gene showing the Exon-1 structure. The filled box represents 5' untranslated region. The hatched box starts at the ATG, and includes the signal sequence. H=HindIII; X=XbaI; N=NcoI; E=EcoRI.

Figure 1B is a diagram of the targeting vector used to disrupt the EphrinB2 gene.

Figure 1C is a schematic representation of the mutated EphrinB2 locus.

5 DETAILED DESCRIPTION OF THE INVENTION

As described herein, it has been shown that arteries and veins are genetically distinct from the earliest stages of embryonic development and that reciprocal interactions between arteries and veins are essential for proper vessel formation. This finding not only changes dramatically our view of the basic ontogenetic anatomy of embryonic vasculature, but also provides the means to distinguish between arterial endothelial cells and venous endothelial cells, both physically and functionally. As a result, means of separating the two cell types from one another; of identifying other artery- or vein-specific genes; of assessing the selective effects of drugs or other agents on arteries or veins and, thus, identifying those which are artery- or vein-specific; and of selectively delivering or targeting substances to either cell type are now available. In addition, the work described herein makes it possible to modulate (enhance or inhibit) or control vasculogenesis and angiogenesis and to do so, if desired, in an artery-specific or vein-specific manner.

Sub D As described in the examples, a gene which encodes a cell membrane-associated ligand which is present in the nervous system and the vascular system has been shown to be expressed by arterial endothelial cells and not by venous endothelial cells. Further, the gene which encodes the receptor for the ligands has been shown to be expressed by venous endothelial cells, but not by arterial endothelial cells. Thus, for the first time, an arterial endothelial cell-(artery-)specific marker and a venous endothelial cell-

*Sub
D1
cont*

(vein-) specific marker are available, making it possible to distinguish between arteries and veins for a variety of purposes, such as further study and understanding of the mechanisms of blood vessel formation; selective targeting of treatments or therapies to arteries or veins (targeting to arteries but not veins or vice versa) and selective modulation (enhancement or inhibition) of formation, growth and survival of arteries and/or veins.

In addition, the work presented in the examples

10 demonstrates that reciprocal signaling between arteries and veins is crucial for vessel morphogenesis (development/formation of arteries and veins). As described, deletion of the ligand-encoding gene in mice prevented the proper development of both arterial and venous vessels. Since the

15 ligand is present on arteries (but not veins), the occurrence of the venous defect is evidence that veins require a signal from arteries for vessel morphogenesis. Conversely, since the arteries are also defective in the mutant mice, the ligand must have a function in the arterial

20 cells themselves, in addition to its role in signaling to the veins. In view of the fact the ligand present on arterial endothelial cells is a transmembrane structure, it most likely functions to receive and transduce to arterial cells a reciprocal signal from venous cells.

25 Specifically, a ligand which is a member of the Ephrin family of Eph family receptor interactive proteins (Eph family of transmembrane ligands) has been shown to be expressed by arterial endothelial cells, but not by venous endothelial cells. Thus, it is now possible to distinguish

30 between or target arteries and veins by relying on the presence or absence of an Ephrin family ligand and its receptor, which is a member of the Eph family of receptor protein-tyrosine kinases. As described herein, arterial endothelial cells have been shown to express EphrinB2 and

venous endothelial cells have been shown to express EphB4, which is an EphrinB2 receptor. EphrinB2 is not expressed on venous endothelial cells and EphB4 is not expressed on arterial endothelial cells, providing a means by which the 5 two cell types can be identified or distinguished and, thus, a means by which arterial endothelial cells and venous arterial cells can be, for example, separated from one another, targeted specifically or acted upon in a selective manner (e.g., by a drug or agent which acts upon one cell 10 type to the exclusion of the other).

The work described herein, particularly in the examples, refers to EphrinB2 and EphB4. However, any ligand-receptor pair from the Ephrin/Eph family, any other ligand-receptor pair or any gene product produced by one 15 cell type and not the other (e.g., an Ephrin ligand is expressed by arterial endothelial cells but not by venous endothelial cells and an Eph receptor is expressed by venous endothelial cells but not by arterial endothelial cells) can be used to distinguish between or identify and, thus, 20 selectively act upon, arterial endothelial cells and venous arterial cells.

The ephrins (ligands) are of two structural types, which can be further subdivided on the basis of sequence relationships and, functionally, on the basis of the 25 preferential binding they exhibit for two corresponding receptor subgroups. Structurally, there are two types of ephrins: those which are membrane-anchored by a glycerophosphatidylinositol (GPI) linkage and those anchored through a transmembrane domain. Conventionally, the ligands 30 are divided into the Ephrin-A subclass, which are GPI-linked proteins which bind preferentially to EphA receptors and the ephrinB subclass, which are transmembrane proteins which generally bind preferentially to EphB receptors.

DRAFT - 2008-02-05 - 001

The Eph family receptors are a family of receptor protein-tyrosine kinases which are related to Eph, a receptor named for its expression in an erythropoietin-producing human hepatocellular carcinoma cell line. They 5 are divided into two subgroups on the basis of the relatedness of their extracellular domain sequences and their ability to bind preferentially to ephrinA proteins or ephrinB proteins. Receptors which interact preferentially with ephrinA proteins are EphA receptors and those which 10 interact preferentially with ephrinB proteins are EphB receptors.

As used herein, the terminology Ephrin and Eph are used to refer, respectively, to ligands and receptors. They can be from any of a variety of animals (e.g., mammals/ 15 nonmammals, vertebrates/nonvertebrates, including humans). The nomenclature in this area has changed rapidly and the terminology used herein is that proposed as a result of work by the Eph Nomenclature Committee, which can be accessed, along with previously-used names at web site <http://www.ehpnomenclature.com>. For convenience, eph receptors and their 20 respective ligand(s) are given in the Table.

The work described herein has numerous research and clinical applications, which are discussed below.

Sub-D2 As used herein, a transgenic mouse is one which has, incorporated into the genome of some or all its nucleated 5 cells, a genetic alteration which has been introduced into the mouse or at least one of its ancestors, by the manipulations of man. A transgenic mouse can result, for example, from the introduction of DNA into a fertilized mouse ovum or from the introduction of DNA into embryonic 10 stem cells.

One embodiment of the present invention is a transgenic mouse, which because of its particular genotype, expresses only in cells of veins or only in cells of arteries a gene whose RNA transcript or polypeptide gene product can be 15 detected, for example, by *in situ* hybridization of RNA, by fluorescence, by detection of enzymatic activity, or by detection of a gene product by antibody binding and a detection system for the bound antibodies.

A particular embodiment of the present invention is a 20 transgenic mouse of genotype *EphrinB2^{+/−}*, wherein the "minus" allele denotes an allele in which a naturally occurring allele has been deleted, modified or replaced with a mutant allele, including a mutant allele which can have an insertion of an indicator gene. Such a "minus" allele can 25 encode an EphrinB2 ligand which has wild type, altered or no ligand function. A mouse of genotype *EphrinB2^{+/−}t^{lacZ}* has been produced as described in Example 1 and used to demonstrate that arterial endothelial cells and venous endothelial cells differ genetically from early stages of development and that 30 reciprocal interactions, essential for proper capillary bed formation, occur between the two types of vessels. A transgenic mouse of the same phenotype can be produced by other methods known to those of skill in the art. These methods are illustrated below using the EphrinB2 gene as an

example, but can also be used for any other vein- or artery-specific gene.

For example, it is possible to produce a vector carrying an insertion, a deletion, or one or more point 5 mutations in the EphrinB2 gene. The EphrinB2 transgene can be introduced into the genome, via a vector carrying a mutagenized EphrinB2 allele, either by introducing the transgene into a fertilized ovum, by the method of Wagner et al., US 4,873,191 (1989), or by introducing the transgene 10 into embryonic stem (ES) cells (see, for example, Capecchi, M.R., *Science* 244:1288-1292, 1989), or by other methods.

An insertion of DNA used to construct a transgenic knockout mouse can have within it a gene whose presence can be readily tested, such as *neo*, which confers upon its host 15 cells resistance to G418. It is an advantage of an *EphrinB2⁺⁻* indicator mouse (e.g., *EphrinB2⁺⁻/tau^{lacZ}*) to be able to express, under the control of the EphrinB2 promoter, an indicator gene, which can be any gene not endogenously expressed by mice. A particularly advantageous indicator 20 gene is one which facilitates the detection of EphrinB2 expression, presumably as it is occurring in the wild type allele, by the production of a gene product that is detectable, for example, by its own light absorbance properties, its ability to act upon a substrate to yield a 25 colored product, or its ability to bind to an indicator or dye which is itself detectable.

Further, alternative methods are available to produce conditional knockouts or tissue specific knockouts of a gene expressed specifically in veins or in arteries (i.e., a vein-specific or artery-specific gene), for example by a site-specific recombinase such as Cre (acting at *loxP* site) or FLP1 (acting at *FRP* site) of yeast.

The bacteriophage P1 Cre-*loxP* recombination system is capable of mediating *loxP* site-specific recombination in

both ES cells and transgenic mice. The site-specific recombinase Cre can also be used in a predefined cell lineage or at a certain stage of development. See, for example, Gu, H. et al., *Science* 265:103-106, 1994, in which 5 a DNA polymerase β gene segment was deleted from T cells; see also Tsien, J.Z. et al., *Cell* 87:1317-1326, 1996, in which *Cre/loxP* recombination was restricted to cells in the mouse forebrain.) The impact of the mutation on these cells can then be analyzed.

10 The Cre recombinase catalyzes recombination between 34
bp *loxP* recognition sequences (Sauer, B. and Henderson, N.,
Proc. Natl. Acad. Sci. USA 85:5166-5170, 1988). The *loxP*
sequences can be inserted into the genome of embryonic stem
cells by homologous recombination such that they flank one
15 or more exons of a gene of interest (making a "floxed"
gene). It is crucial that the insertions do not interfere
with normal expression of the gene. Mice homozygous for the
floxed gene are generated from these embryonic stem cells by
conventional techniques and are crossed to a second mouse
20 that harbors a Cre transgene under the control of a tissue
type- or cell type-specific transcriptional promoter. In
progeny that are homozygous for the floxed gene and that
carry the Cre transgene, the floxed gene will be deleted by
Cre/*loxP* recombination, but only in those cell types in
25 which the Cre gene-associated promoter is active.

A gene that encodes a protein which acts to have the effect of mimicking the phenotype caused by mutations in a vein-specific or artery-specific gene can also be used to achieve the same effect as knockouts in vein-specific or artery-specific genes.

A mutation in a gene which encodes a product which prevents binding of ligand to receptor or prevents the functional consequences of such binding and thereby duplicates the phenotype of a vein- or artery-specific gene

knockout (e.g., a dominant negative mutant) can be used as an alternative to a knockout. The mutated gene can be put under the control of a tissue-specific promoter to be expressed in vein or artery, depending on the tissue-
5 specific gene product whose function is to be inhibited.

In addition, one or more dominant negative alleles of an artery-specific or vein-specific gene can be put under the control of an inducible promoter so that upon induction, the effect of the inhibition of gene function can be
10 studied. A dominant negative mutant can be isolated or constructed by mutagenesis and methods to make a transgenic mouse.

Testing to identify the desired mutant or wild type alleles, or for the identification of other alleles, can be
15 done by PCR on isolated genomic DNA, using appropriate primers, or by Southern blots using appropriate hybridization probes, by a combination of these procedures, or by other methods.

In addition to the uses of an indicator mouse described
20 in the Examples herein, one use of a mouse having an indicator gene which can mark artery cells is a method for testing an effect of a drug on growth of arteries. The method can comprise administering the drug to a mouse (e.g., embryo, neonate, juvenile, adult, a wound site) having an
25 indicator gene inserted in a gene specifically expressed in arteries, and observing the effect of the drug on the growth of the arteries, compared to the effect in a suitable control mouse having an indicator gene, not treated with the drug, but maintained under identical conditions. Similar
30 tests may be performed on an indicator mouse having an indicator gene which marks vein cells. The effect of the drug can be, for example, to promote growth, to inhibit growth, or to promote aberrant growth. Administration of

the drug can be by any suitable route known to those of skill in the art.

An indicator mouse having an indicator gene inserted in a gene specifically expressed in artery cells can be crossed 5 with a mouse of another strain carrying a mutation in a gene which is to be tested for its effect on the growth and development of blood vessels, to allow for easier visualization of the effects of the mutation specifically on artery cells. In tests similar to those described above, 10 the effect of a drug can be assessed on the mouse which results from this type of cross, to see, for example, whether the effect of the mutation can be alleviated by the drug. In like manner, an indicator mouse having an indicator gene inserted in a gene specifically expressed in 15 vein cells can be used in a cross with a mouse with a mutation whose effect on growth of veins is to be evaluated, and the resulting hybrid used in studies of the growth of veins.

July 23 As a result of the work described herein, it is 20 possible to differentiate between arterial endothelial cells (arteries) and venous endothelial cells (veins) by taking advantage of the presence of an artery-specific or vein-specific gene product on the surface of the cells. Arterial endothelial cells and venous endothelial cells can each be 25 isolated from cells of other tissue types by, for instance, excision of artery or vein tissue from a sample of mammalian tissue, dissociation of the cells, allowing the cells to bind, under appropriate conditions, to a substance which has some property or characteristic (e.g., a molecule which 30 provides a label or tag, or molecule that has affinity for both the an artery-specific cell surface protein and another type of molecule) that facilitates separation of cells bound to the substance from cells not bound to the substance. Separation of the cells can take advantage of the properties

of the bound substance. For example, the substance can be an antibody (antiserum, polyclonal or monoclonal) which has been raised against the protein specific to arterial endothelial cells (or to a sufficiently antigenic portion of the protein) and labeled with a fluorochrome, with biotin, or with another label. Separation of cells bound to the substance can be by FACS, for a fluorescent label, by streptavidin affinity column, for a biotin label, by other affinity-based separation methods, or, for example, by antibody-conjugated magnetic beads or solid supports.

Other means of separation can exploit, for blood vessel cells bearing an indicator insertion in a gene encoding an artery- or vein-specific protein, the properties of the indicator gene product or portion of fusion protein encoded by the indicator insertion. For example, cells producing an artery- or vein-specific fusion protein with a green fluorescent protein portion or a blue fluorescent protein portion can be separated from non-fluorescent cells by a cell sorter. Cells producing a fusion protein of an artery- or vein-specific protein portion and an indicator protein or portion with enzymatic or binding activity can be detected by the ability of the fusion protein to bind to a fluorescent substrate, for example a substrate for β -galactosidase or β -lactamase, or to produce a fluorescent product in cells.

The isolation of arterial endothelial cells and the isolation of venous endothelial cells allows for tests of these cell types in culture to assess the effects of various drugs, growth factors, ligands, cytokines, members of the Eph and Ephrin families of receptors and ligands, molecules that bind to cell surface proteins, or other molecules which can have effects on the growth and development of arteries and veins. One or more of these substances can be added to the culture medium, and the effects of these additions can

DRAFT - 05/22/2008

Sut D3

be assessed (e.g., by measurements of growth rate or viability, enzyme assays, assays for the presence of cell surface components, incorporation of labeled precursors into macromolecules such as DNA, RNA or proteins).

5 Isolated arterial endothelial cells or isolated venous endothelial cells can be maintained in artificial growth medium and an immortalized cell line can be produced from such isolated cells (i.e., "transformation") by infection with one of any number of viruses (e.g., retroviruses, by 10 transduction of immortalizing oncogenes such as v-myc or SV40 T antigen) known to effectively transform cells in culture. The virus can be chosen for its species 15 specificity of infectivity (e.g., murine ecotropic virus for mouse cells; amphotropic or pseudotyped viruses for human cells). As an alternative to viral transformation, cells can be maintained in culture by propagating the cells in medium containing one or more growth factors.

Immortalized cell lines derived from either vein or artery cells can be used to produce cDNA libraries to 20 facilitate study of genes actively expressed in each of these tissues. Further, such cell lines can be used to isolate and identify proteins expressed in the cells, for instance, by purifying the proteins from conditioned growth medium or from the cells themselves.

25 As one alternative to using immortalized cell lines of arterial or venous origin, cells or cell lines of non-arterial origin or non-venous origin (e.g., endothelial cells from other tissues, or fibroblasts) can be genetically altered (by the introduction of one or more non-endogenously 30 expressed genes) to express an artery-specific or vein-specific cell surface protein, and used in methods to detect and identify substances that interfere with receptor-ligand interaction.

Introduction of one or more genes into a cell line can be, for instance, by transformation, such as by electroporation, by calcium phosphate, DEAE-dextran, or by liposomes, using a vector which has been constructed to have 5 an insertion of one or more genes. See Ausubel, F.M. et al, *Current Protocols in Molecular Biology*, chapter 9, containing supplements through Supplement 40, Fall, 1997, John Wiley & Sons, New York. The introduction of one or more genes to be expressed in a cell line can also be 10 accomplished by viral infection, for example, by a retrovirus. Retroviral gene transfer has been used successfully to introduce genes into whole cell populations, thereby eliminating problems associated with clonal variation.

15 The ability to differentiate and to isolate the cells of veins and arteries allows for a wide variety of applications for a wide variety of purposes. For example, it is now possible to assess the effects of various agents, such as drugs, diagnostic reagents and environmental/dietary 20 factors, on arteries and veins and to determine if the effects observed are common to both types of cells or specific to one cell type.

For example, it can no longer be assumed that angiogenic and anti-angiogenic factors or drugs act equivalently on arterial and venous cells. Isolation and separation of these two cell types, which is made possible by the present work, allows testing of these angiogenic and anti-angiogenic factors for arterial or venous specificity, which will provide more selective clinical indications for these drugs. It will also allow the discovery of new artery- or vein-selective drugs, such as by high-throughput screening of immortalized arterial or venous endothelial cell lines. Existing drugs can also be selectively targeted to arteries or veins by using the proteins described herein

as vectors (e.g., viral vehicles having the protein on the viral surface) to deliver drugs (e.g., chemically coupled drugs) to one type of vessel or the other.

There are numerous approaches to screening agents for
5 their selective effects (angiogenic or anti-angiogenic) on arteries and veins. For example, high-throughput screening of compounds or molecules can be carried out to identify angiogenic or anti-angiogenic agents or drugs which act selectively on arteries or veins or, in some cases, on both.
10 Compounds or molecules which are assessed by such a screening method can be from a wide variety of sources, such as chemical libraries, cell culture broth or media, cells which have been processed to render their contents available for screening (plant or animal tissue extracts, for example)
15 and combinatorial libraries. The compounds or molecules (referred to collectively as agents or drugs) which are screened can be those already known to have angiogenic or anti-angiogenic activity or those of unknown effectiveness. In the former case, the screening will be useful to identify
20 those drugs which act selectively on arterial endothelial cells or on venous endothelial cells and in the latter, it will be useful to newly identify drugs which have angiogenic or antiangiogenic activity and to establish the cell type (arterial, venous) on which they act. For example,
25 immortalized cell lines of arterial or venous origin can be used to screen libraries of compounds to identify drugs with artery- or vein- specific angiogenic or anti-angiogenic effects. In one embodiment, an assay can be carried out to screen for drugs that specifically inhibit binding of an
30 Ephrin ligand to its Eph receptor, such as binding of EphrinB2 to the EphB4 receptor, or vice-versa, by inhibition of binding of labeled ligand- or receptor-Fc fusion proteins to immortalized cells. Alternatively, such libraries can be screened to identify members which enhance binding of an

Ephrin ligand to its Eph receptor by enhancing binding of labeled ligand- or receptor-Fc fusion proteins to immortalized cells. Drugs identified through this screening can then be tested in animal models (e.g., models of cancer, 5 arteriovenous malformations or coronary artery disease) to assess their activity *in vivo*.

Sub-D4 A drug that inhibits interaction of an artery-specific cell surface molecule (e.g., an arterial endothelial cell-specific surface molecule) with a vein-specific cell surface 10 molecule (e.g., a venous endothelial cell-specific surface molecule) can be identified by a method in which, for example, the arterial endothelial cell-specific surface molecule and the venous endothelial cell-specific surface 15 molecule are combined with a drug to be assessed for its ability to inhibit interaction between the cell-specific molecules, under conditions appropriate for interaction between the cell-specific molecules. The cell-specific molecules may be used in the assay such that both are found on intact cells in suspension (e.g., isolated arterial or 20 venous endothelial cells, immortalized cells derived from these, or cells which have been modified to express an artery- or vein-specific cells surface molecule); one cell type is fixed to a solid support, and the other molecule specific to the other cell type is in soluble form in a 25 suitable solution; or the molecule specific to one cell type is fixed to a solid support while the molecule specific to the other cell type is found free in a solution that allows for interaction of the cell-specific molecules. Other variations are possible to allow for the convenient 30 assessment of the interaction between the two different cell-specific molecules.

In further steps of the assay, the extent to which the cell-specific molecules interact is determined, in the presence of the drug, and in a separate test (control), in

the absence of the drug. The extent to which interaction of the cell-specific molecules occurs in the presence and in the absence of the drug to be assessed is compared. If the extent to which interaction of the cell-specific molecules 5 occurs is less in the presence of the drug than in the absence of the drug, the drug is one which inhibits interaction of the arterial endothelial cell-specific molecule with the venous endothelial cell-specific molecule. If the extent to which interaction of the cell-specific 10 molecules occurs is greater in the presence of the drug than in the absence of the drug, the drug is one which enhances interaction of the arterial endothelial cell-specific molecule with the venous endothelial cell-specific molecule.

In one embodiment of an assay to identify a substance 15 that interferes with interaction of two cell surface molecules, one specific to artery and the other specific to vein (e.g., binding of a ligand to a receptor that recognizes it; interaction between adhesion proteins; interaction between a cell surface protein and a 20 carbohydrate moiety on a cell surface), samples of cells expressing one type of cell surface molecule (e.g., cells expressing an Eph receptor, such as a vein-derived cell line or other cells genetically manipulated to express the Eph receptor) are contacted with either labeled ligand 25 (e.g., an ephrin ligand, a soluble portion thereof, or a soluble fusion protein such as a fusion of the extracellular domain and the Fc domain of IgG) or labeled ligand plus a test compound or group of test compounds. The amount of labeled ligand which has bound to the cells is determined. 30 A lower amount of label (where the label can be, for example, a radioactive isotope, a fluorescent or colormetric label) in the sample contacted with the test compound(s) is an indication that the test compound(s) interferes with binding. The reciprocal assay using cells expressing a

ligand (e.g., an Ephrin ligand or a soluble form thereof) can be used to test for a substance that interferes with the binding of a receptor or soluble portion thereof.

An assay to identify a substance which interferes with

5 interaction between artery-specific and vein-specific cell surface protein can be performed with the component (e.g., cells, purified protein, including fusion proteins and portions having binding activity) which is not to be in competition with a test compound, linked to a solid support.

10 The solid support can be any suitable solid phase or matrix, such as a bead, the wall of a plate or other suitable surface (e.g., a well of a microtiter plate), column pore glass (CPG) or a pin that can be submerged into a solution, such as in a well. Linkage of cells or purified protein to

15 the solid support can be either direct or through one or more linker molecules.

Upon the isolation from a mammal of a gene expressing an artery-specific or a vein-specific protein, the gene can be incorporated into an expression system for production of

20 a recombinant protein or fusion protein, followed by isolation and testing of the protein *in vitro*. The isolated or purified protein can also be used in further structural studies that allow for the design of agents which specifically bind to the protein and can act as agonists or

25 antagonists of the receptor or ligand activity of the protein.

In one embodiment, an isolated or purified artery-specific or vein-specific protein can be immobilized on a suitable affinity matrix by standard techniques, such as

30 chemical cross-linking, or via an antibody raised against the isolated or purified protein, and bound to a solid support. The matrix can be packed in a column or other suitable container and is contacted with one or more compounds (e.g., a mixture) to be tested under conditions

suitable for binding of the compound to the protein. For example, a solution containing compounds can be made to flow through the matrix. The matrix can be washed with a suitable wash buffer to remove unbound compounds and non-
5 specifically bound compounds. Compounds which remain bound can be released by a suitable elution buffer. For example, a change in the ionic strength or pH of the elution buffer can lead to a release of compounds. Alternatively, the elution buffer can comprise a release component or
10 components designed to disrupt binding of compounds (e.g., one or more ligands or receptors, as appropriate, or analogs thereof which can disrupt binding or competitively inhibit binding of test compound to the protein).

Fusion proteins comprising all of, or a portion of, an artery-specific or a vein-specific protein linked to a second moiety not occurring in that protein as found in nature can be prepared for use in another embodiment of the method. Suitable fusion proteins for this purpose include those in which the second moiety comprises an affinity
20 ligand (e.g., an enzyme, antigen, epitope). The fusion proteins can be produced by the insertion of a gene specifically expressed in artery or vein cells or a portion thereof into a suitable expression vector, which encodes an affinity ligand. The expression vector can be introduced
25 into a suitable host cell for expression. Host cells are disrupted and the cell material, containing fusion protein, can be bound to a suitable affinity matrix by contacting the cell material with an affinity matrix under conditions sufficient for binding of the affinity ligand portion of the
30 fusion protein to the affinity matrix.

In one aspect of this embodiment, a fusion protein can be immobilized on a suitable affinity matrix under conditions sufficient to bind the affinity ligand portion of the fusion protein to the matrix, and is contacted with one

or more compounds (e.g., a mixture) to be tested, under conditions suitable for binding of compounds to the receptor or ligand protein portion of the bound fusion protein. Next, the affinity matrix with bound fusion protein can be 5 washed with a suitable wash buffer to remove unbound compounds and non-specifically bound compounds without significantly disrupting binding of specifically bound compounds. Compounds which remain bound can be released by contacting the affinity matrix having fusion protein bound 10 thereto with a suitable elution buffer (a compound elution buffer). In this aspect, compound elution buffer can be formulated to permit retention of the fusion protein by the affinity matrix, but can be formulated to interfere with binding of the compound(s) tested to the receptor or ligand 15 protein portion of the fusion protein. For example, a change in the ionic strength or pH of the elution buffer can lead to release of compounds, or the elution buffer can comprise a release component or components designed to disrupt binding of compounds to the receptor or ligand 20 protein portion of the fusion protein (e.g., one or more ligands or receptors or analogs thereof which can disrupt binding of compounds to the receptor or ligand protein portion of the fusion protein).

Immobilization can be performed prior to, simultaneous 25 with, or after contacting the fusion protein with compound, as appropriate. Various permutations of the method are possible, depending upon factors such as the compounds tested, the affinity matrix selected, and elution buffer formulation. For example, after the wash step, fusion 30 protein with compound bound thereto can be eluted from the affinity matrix with a suitable elution buffer (a matrix elution buffer). Where the fusion protein comprises a cleavable linker, such as a thrombin cleavage site, cleavage from the affinity ligand can release a portion of the fusion

DRAFT

Page 25 of 25

with compound bound thereto. Bound compound can then be released from the fusion protein or its cleavage product by an appropriate method, such as extraction.

One or more compounds can be tested simultaneously according to the method. Where a mixture of compounds is tested, the compounds selected by the foregoing processes can be separated (as appropriate) and identified by suitable methods (e.g., PCR, sequencing, chromatography). Large combinatorial libraries of compounds (e.g., organic compounds, peptides, nucleic acids) produced by combinatorial chemical synthesis or other methods can be tested (see e.g., Ohlmeyer, M.H.J. et al., *Proc. Natl. Acad. Sci. USA* 90:10922-10926 (1993) and DeWitt, S.H. et al., *Proc. Natl. Acad. Sci. USA* 90:6909-6913 (1993), relating to tagged compounds; see also, Rutter, W.J. et al., U.S. Patent No. 5,010,175; Huebner, V.D. et al., U.S. Patent No. 5,182,366; and Geysen, H.M., U.S. Patent No. 4,833,092). Where compounds selected from a combinatorial library by the present method carry unique tags, identification of individual compounds by chromatographic methods is possible. Where compounds do not carry tags, chromatographic separation, followed by mass spectrophotometry to ascertain structure, can be used to identify individual compounds selected by the method, for example.

An *in vivo* assay useful to identify drugs which act selectively on arteries or on veins is also available. It is carried out using transgenic animals, such as those described herein, which make it possible to visualize angiogenic processes. For example, an EphrinB2 knockout mouse containing a marker, such as a tau-lacZ insertion, that marks all arteries but not veins can be used for a variety of *in vivo* assays. Other marker genes that can be used, for instance, are genes expressing alkaline phosphatase, blue fluorescent protein or green fluorescent

protein. The mouse, or the targeted allele it contains, can be used to study angiogenic processes, such as tumor angiogenesis and ischemia-associated cardiac neovascularization, in arteries, independent of veins. For 5 example, tumor cells can be implanted in the indicator mouse and arterial vessel growth into the tumor can be visualized by *lacZ* staining. Alternatively, mice bearing the targeted allele can be crossed with a mouse model of another condition, such as vascular degeneration or 10 neovascularization, to be visualized. The arterial-specific aspects of the process can be visually monitored by *lacZ* staining. An indicator of this type can also be used to assess drugs for their angiogenic or anti-angiogenic effects.

15 A gene product produced specifically by arterial endothelial cells (arteries) and not by other cell types allows for the specific targeting of drugs, diagnostic agents, tagging labels, histological stains or other substances specifically to arteries. In an analogous 20 manner, a gene product identified as produced specifically by venous endothelial cells (veins) and not detectably produced by other cell types allows for the specific targeting and delivery of drugs, diagnostic agents, tagging labels, histological stains or other substances specifically 25 to veins. The following description of targeting vehicles, targeted agents and methods is presented using EphrinB2 as an illustration of a gene product produced by arterial endothelial cells and not by vein cells and EphB4 as an illustration of a gene product produced by venous 30 endothelial cells and not by artery cells. However, this description applies equally well to other artery-specific and vein-specific gene products that can be used to identify these tissue types.

00025320-052000

Jul 05 > The differential expression of EphrinB2 in arteries and of Eph4 in veins allows for the specific targeting of drugs, diagnostic agents or other substances to the cells of arteries or of veins. A targeting vehicle can be used for 5 the delivery of such a substance. Targeting vehicles which bind specifically to EphrinB2 or to Eph4 can be linked to a substance to be delivered to the cells of arteries or veins, respectively. The linkage can be via one or more covalent bonds, or by high affinity non-covalent bonds. A targeting 10 vehicle can be an antibody, for instance, or other compound which binds either to EphrinB2 or to EphB4 with high specificity. Another example is an aqueously soluble polypeptide having the amino acid sequence of the extracellular domain of EphB4, or a sufficient portion of 15 the extracellular domain (or a polypeptide having an amino acid sequence conferring a similar enough conformation to allow specific binding to EphrinB2), which can be used as a targeting vehicle for delivery of substances to EphrinB2 in arteries. Similarly, a soluble polypeptide having the amino 20 acid sequence of the extracellular domain of EphrinB2 or a sufficient antigenic portion of the extracellular domain (or a polypeptide having an amino acid sequence conferring a similar enough conformation to allow specific binding to EphB4), can be used to target substances to EphB4 in veins.

25 Targeting vehicles specific to an artery-specific Ephrin ligand (e.g., EphrinB2) or to a vein-specific Eph receptor (e.g., EphB4) have in vivo (e.g., therapeutic and diagnostic) applications. For example, an antibody which specifically binds to EphrinB2 can be conjugated to a drug 30 to be targeted to arteries (e.g., a therapeutic, such as an anti-plaque agent). Alternatively, an antibody which specifically binds to EphB4 can be used to target a drug to veins. A substance (e.g., a radioactive substance) which can be detected (e.g., a label) in vivo can also be linked

to a targeting vehicle which specifically binds to an artery-specific Ephrin ligand (e.g., EphrinB2) and the conjugate can be used as a labeling agent to identify arteries. Similarly, a detectable label can be linked to a targeting vehicle which specifically binds a vein-specific Eph receptor (e.g., EphB4) to identify veins.

Targeting vehicles specific to EphrinB2 or to EphB4 find further applications in vitro. For example, an EphB4-specific targeting vehicle, such as an antibody (a polyclonal preparation or monoclonal) which specifically binds to EphB4, can be linked to a substance which can be used as a stain for a tissue sample (e.g., horseradish peroxidase) to provide a method for the identification of veins in a sample. Likewise, an antibody which specifically binds to EphrinB2 can be used in the identification of arteries. For instance, in a biopsied tissue sample, as from a tumor, antibody to EphrinB2 can be used to identify artery tissue and to distinguish it from vein tissue, or to identify malformed arteries.

To treat malformed, painful or cosmetically undesirable veins, an agent which acts against them (e.g., antiangiogenic factors) can be linked to an EphB4-specific vehicle for local administration to the veins. For example, antiangiogenic factors can be injected into varicose veins.

Targeted agents directed to either an artery-specific Ephrin family ligand (e.g., EphrinB2) or a vein-specific Eph family receptor (e.g., EphB4) can also be used when it is desired to produce an effect on both arteries and veins. For example, limited amounts of targeted agents comprising an anti-angiogenic drug and a targeting vehicle to either EphrinB2, EphB4, or both, can be administered locally to sites of angiogenesis, such as sites of tumor formation where it is desired to inhibit the growth of blood vessels,

or to areas in which increased vascularization is desired to enhance growth or establishment of blood vessels.

Substances that act as agonists or antagonists of an artery-specific Ephrin family ligand (e.g., EphrinB2) or a 5 vein-specific Eph family receptor (e.g., EphB4) can be used as angiogenic or anti-angiogenic agents. Drugs that target these molecules will selectively influence arterial and venous angiogenesis. For example, monoclonal antibodies to EphrinB2 or EphB4 can serve as artery- or vein-specific 10 angiogenic or anti-angiogenic agents. As can be concluded from the phenotype shown by the *EphrinB2^{t_{lacZ}}*/*EphrinB2^{t_{lacZ}}* mutant mice, antagonists of EphrinB2 or antagonists of EphB4 will inhibit angiogenesis. Agents which are agonists of both EphrinB2 and EphB4 will promote angiogenesis.

15 In another example, soluble agonists which comprise the extracellular domain of an Ephrin family ligand or the extracellular domain of an Eph family receptor fused to the Fc domain of human IgG can be produced. For example, an EphB4 or an EphrinB2 hybrid protein in which the 20 extracellular domain of the membrane protein is fused to the Fc domain of human IgG can be used (Wang, H.U. and D.J. Anderson, *Neuron* 18:383-396 (1997)). See, for examples of methods Stein, E. et al., *Genes and Dev.* 12:667-678 (1998), regarding experiments on responses of cells to clustered 25 Ephrin-B1/Fc fusion proteins. Clustering of these hybrid molecules with anti-human Fc antibodies generates soluble agonists: Ephrin-derived "ligand-bodies" for Eph receptors, and conversely, Eph-derived "receptor bodies" for Ephrins. Non-clustered forms of these hybrid molecules can be used as 30 antagonists.

A further application of isolated arterial endothelial cells and isolated venous endothelial cells is the genetic alteration of the isolated cells and the administration of these cells, preferably intravenously, to the host mammal

from which the cells were isolated, or into another compatible host, where the cells can be incorporated into a blood vessel of the appropriate type. In this way, the effects of a genetic defect which is manifested in arteries 5 or in veins can be ameliorated. It has been demonstrated that circulating endothelial cell progenitors can migrate to sites of neovascularization and be incorporated into blood vessels (Asahara et al., *Science* 275:964-967 (1997)).

The introduction of a gene (an endogenous gene that has 10 been altered, or a gene originally isolated from a different organism, for example) into cells can be accomplished by any of several known techniques, for example, by vector mediated gene transfer, as by amphotropic retroviruses, calcium phosphate, or liposome fusion, for example.

15 A gene intended to have an effect on arteries or veins in a host mammal can be delivered to isolated artery cells or isolated vein cells by the use of viral vectors comprising one or more nucleic acid sequences encoding the gene of interest. Generally, the nucleic acid sequence has 20 been incorporated into the genome of the viral vector. *In vitro*, the viral vector containing the nucleic acid sequences encoding the gene can be contacted with a cell and infection can occur. The cell can then be used experimentally to study, for example, the effect of the gene 25 on growth of artery or vein cells *in vitro* or the cells can be implanted into a patient for therapeutic use. The cells to be altered by introduction or substitution of a gene can be present in a biological sample obtained from the patient and used in the treatment of disease, or can be obtained 30 from cell culture and used to dissect developmental pathways of arteries and veins in *in vivo* and *in vitro* systems.

After contact with the viral vector comprising a nucleic acid sequence encoding the gene of interest, the treated artery or vein cells can be returned or

readministered to a patient according to methods known to those practiced in the art. Such a treatment procedure is sometimes referred to as *ex vivo* treatment. *Ex vivo* gene therapy has been described, for example, in Kasid, et al., 5 *Proc. Natl. Acad. Sci. USA* 87:473 (1990); Rosenberg, et al., *New Engl. J. Med.* 323:570 (1990); Williams, et al., *Nature* 310:476 (1984); Dick, et al., *Cell* 42:71 (1985); Keller, et al., *Nature* 318:149 (1985) and Anderson, et al., U.S. Patent No. 5,399,346 (1994).

10 Generally, viral vectors which can be used therapeutically and experimentally are known in the art. Examples include the vectors described by Srivastava, A., U.S. Patent No. 5,252,479 (1993); Anderson, W.F., et al., U.S. Patent No. 5,399,346 (1994); Ausubel et al., "Current 15 Protocols in Molecular Biology", John Wiley & Sons, Inc. (1998). Suitable viral vectors for the delivery of nucleic acids to cells include, for example, replication defective retrovirus, adenovirus, parvovirus (e.g., adeno-associated viruses), and coronavirus. Examples of retroviruses include 20 avian leukosis-sarcoma, mammalian C-type, B-type viruses, lentiviruses (Coffin, J.M., "Retroviridae: The Viruses and Their Replication", In: *Fundamental Virology*, Third Edition, B.N. Fields, et al., eds., Lippincott-Raven Publishers, Philadelphia, PA, (1996)). The mechanism of infectivity 25 depends upon the viral vector and target cell. For example, adenoviral infectivity of HeLa cells occurs by binding to a viral surface receptor, followed by receptor-mediated endocytosis and extrachromosomal replication (Horwitz, M.S., "Adenoviruses" In: *Fundamental Virology*, Third Edition, B.N. 30 Fields, et al., eds., Lippincott-Raven Publishers, Philadelphia, PA, (1996)).

The present invention is illustrated by the following examples, which are not intended to be limiting in any way.

EXAMPLES

Experimental Procedures

The following experimental procedures were used in the examples which follow.

5 Targeted disruption of the *EphrinB2* gene. A 200 base pair probe starting from the ATG of the mouse *EphrinB2* gene (Bennett, B. D., et al., *Proc. Natl. Acad. Sci. USA* 92:1866-1870 (1995)) was used to screen a 129SVJ genomic library (Stratagene). Analysis of several overlapping clones

10 revealed that the first exon, including the signal sequence, ends at 131 base pairs after the ATG. Further phage analysis and library screens revealed that the rest of the *EphrinB2* gene was located at least 7 kb downstream from the first exon. To construct a targeting vector (Fig. 1B), a

15 3kb XbaI-NcoI fragment whose 3' end terminated at the ATG was used as the 5' arm. A 5.3 kb Tau-lacZ coding sequence (Mombaerts, P., et al., *Cell* 87:675-686 (1996)) was fused in frame after the ATG. The PGKneo gene (Ma, Q., et al., *Neuron* 20:469-482 (1998)) was used to replace a 2.8 kb

20 intronic sequence 3' to the first exon. Finally, a 3.2 kb downstream EcoRI-EcoRI fragment was used as the 3' arm. Normal (6kb) and targeted (9kb) loci are distinguished by HindIII digestion when probed with a 1kb HindIII-XbaI genomic fragment. Electroporation, selection and

25 blastocyst-injection of AB-1 ES cells were performed essentially as described Ma, Q., et al. (*Neuron* 20:469-482 (1998)), with the exception that FIAU-selection was omitted. ES cell targeting efficiency via G418 selection was 1 out of 18 clones. Germline transmission of the targeted *EphrinB2*

30 locus (Fig. 1C) in heterozygous males was confirmed by Southern blotting of tail DNA of adult mice, using a 1kb

HindIII-XbaI probe. Subsequent genotyping was done by genomic PCR. Primers for Neo are 5'-AAGATGGATTGCACGCAGGTTCTC-3' (SEQ ID NO.: 1) and 5'-CCTGATGCTCTCGTCCAGATCAT-3' (SEQ ID NO.: 2). Primers for 5 the replaced intronic fragment are 5'-AGGACGGAGGACGTTGCCACTAAC-3' (SEQ ID NO.: 3) and 5'-ACCACCAGTTCCGACGCGAAGGGA-3' (SEQ ID NO.: 4).

LacZ, PECAM-1, and histological staining. Embryos and yolk sacs were removed between E7.5 and E10.0, fixed in cold 10 4% paraformaldehyde/PBS for 10 minutes, rinsed twice with PBS, and stained for 1 hour to overnight at 37°C in X-gal buffer (1.3 mg/ml potassium ferrocyanide, 1 mg/ml potassium ferricyanide, 0.2% Triton X-100, 1mM MgCl₂, and 1mg/ml X-gal in PBS, pH 7.2). LacZ stained embryos were post-fixed and 15 photographed, or sectioned on a cryostat after embedding in 15% sucrose and 7.5% gelatin in PBS. Procedures for whole mount or section staining with anti-PECAM-1 antibody (clone MEC 13.3, Pharmingen) were done essentially as described Ma et al. (Neuron 20:469-482 (1998); Fong et al., *Nature* 20 376:66-70 (1995)). Horseradish peroxidase-conjugated secondary antibodies were used for all PECAM-1 stainings. LacZ-stained yolk sacs were sectioned in gelatin and then subjected to hematoxylin counter-staining by standard procedures.

25 In situ hybridization. In situ hybridization on frozen sections was performed as previously described (Birren et al. *Development* 119:597-610 (1993)). Whole-mount in situ hybridization followed a protocol by Wilkinson, D.G., (Whole-mount in situ hybridization of vertebrate embryos. 30 pp. 75-83 In: *In Situ Hybridization: A Practical Approach* (ed. D.G. Wilkinson) *IRL Press, Oxford* :75-83 (1992). Bluescript vectors (Stratagene) containing cDNAs for EphB2/Nuk and EphB4/Myk-1 were generated as described Wang, H.U. and Anderson, D.J. (*Neuron* 18:383-396 (1997)).

Example 1: Targeted mutagenesis of *EphrinB2* in mice

Targeted disruption of the *EphrinB2* gene was achieved by homologous recombination in embryonic stem cells. The targeting strategy involved deleting the signal sequence and 5 fusing a *tau-lacZ* indicator gene in frame with the initiation codon. The expression pattern of β -galactosidase in heterozygous (*EphrinB2^{flacZ/+}*) embryos was indistinguishable from that previously reported for the endogenous gene.

(Bennett, B.D. et al. *Proc. Natl. Acad. Sci. USA* 92: 1866-10 1870 (1995); Bergemann, A.D. et al. *Mol. Cell. Bio.* 1995:4921-4929 (1995); Wang, H.U. and Anderson, D.J. *Neuron* 18:383-396 (1997)). While prominent expression was detected in the hindbrain and somites, lower levels were observed in the aorta and heart as early as E8.25. Expression in the 15 yolk sac was first detected at E8.5. Heterozygous animals appeared phenotypically normal. In homozygous embryos, growth retardation was evident at E10 and lethality occurred with 100% penetrance around E11. No expression of endogenous *EphrinB2* mRNA was detected by *in situ* 20 hybridization, indicating that the mutation is a null. Somite polarity, hindbrain segmentation, and the metamerich patterning of neural crest migration (in which *EphrinB2* and related ligands have previously been implicated Xu, W. et al. *Development* 121:4005-4016 (1995); Wang, H.U. and 25 Anderson, D.J. *Neuron* 18:383-396 (1997); Krull, C.E. et al. *Curr. Biol.* 7:571-580 (1997); Smith, A. et al. *Curr. Biol.* 7:561-570 (1997)) appeared grossly normal in homozygous mutant embryos.

Example 2: Reciprocal expression pattern of *EphrinB2* and 30 *EphB4* in arteries and veins

The enlarged heart observed in dying mutant embryos prompted examination of the expression of *EphrinB2^{flacZ}* in the vascular system in detail. Expression was consistently

observed in arteries but not veins. In the yolk sac, for example, the posterior vessels connected to the vitelline artery, but not the vitelline vein, expressed the gene, as detected by lacZ staining. In the trunk, labeling was

5 detected in the dorsal aorta, vitelline artery, umbilical artery and its allantoic vascular plexus, but not the umbilical, anterior and common cardinal veins (the umbilical vein is labeled with anti-PECAM-1 antibody). In the head, labeling was seen in branches of the internal carotid

10 artery, but not in those of the anterior cardinal vein. In situ hybridization with *EphrinB2* cDNA probes confirmed that the selective expression of tau-lacZ in arteries correctly reflected the pattern of expression of the endogenous gene. Examination of the expression of the four *EphB* family genes,

15 as well as Eph A4/Sek1, which are receptors for *EphrinB2* Gale, N.W. et al., *Neuron* 17:9-19 (1996) revealed complementary expression of EphB4 in veins but not arteries, including the vitelline vein and its branches in anterior portion of the yolk sac.

20 Example 3: Vasculogenesis occurs normally in *EphrinB2* mutant embryos

The formation of the major vessels in the trunk was unaffected by the lack of *EphrinB2*, as examined by lacZ and PECAM-1 double staining of 9 somite embryos. Expression of

25 *EphrinB2-lacZ* was seen in the dorsal aorta and vitelline artery, but not the umbilical and posterior cardinal veins. The dorsal aorta, vitelline artery, posterior cardinal and umbilical veins, for example, formed, although some dilation and wrinkling of the vessel wall was observed. Similarly

30 the intersomitic vessels originating from the dorsal aorta formed at this stage. Between E8.5 and E9.0, the primitive endocardium appeared only mildly perturbed in mutants, while a pronounced disorganization was apparent at E10. Red blood

cells developed and circulated normally up to E9.5 in both the mutant yolk sac and embryo proper.

Example 4: Extensive intercalation of yolk sac arteries and veins revealed by *EphrinB2* expression

5 In the yolk sac, the vitelline artery and its capillary network occupy the posterior region, and the vitelline vein and its capillaries the anterior region. At E8.5, a stage at which the primary capillary plexus has formed but remodeling has not yet occurred, asymmetric expression of
10 *EphrinB2-taulacZ* in heterozygous embryos was evident at the interface between the anterior and posterior regions. Apparently homotypic remodeling of β -galactosidase⁺ arterial capillaries into larger, branched trunks clearly segregated from venous vessels was evident between E9.0 and E9.5. At
15 this stage, expression of the receptor EphB4 was clearly visible on the vitelline veins but not arteries. Thus arterial and venous endothelial capillaries are already molecularly distinct following vasculogenesis and prior to angiogenesis.
20 While textbook diagrams (Carlson, B.M Patten's *Foundations of Embryology* (1981)) of the yolk sac capillary plexus depict a non-overlapping boundary between the arterial and venous capillary beds, expression of *EphrinB2-taulacZ* allowed detection of a previously-unrecognized
25 extensive intercalation between arteries and veins across the entire anterior-posterior extent of the yolk sac; this was observed in the heterozygote, but not in the homozygote. Double-labeling for PECAM and β -galactosidase revealed that the interface between the arteries and veins occurs between
30 microvessel extensions that bridge larger vessels interdigitating en passant.

Example 5: Disrupted angiogenesis in the yolk sac of *EphrinB2*^t*lacZ* / *EphrinB2*^t*lacZ* embryos

but the Defects in yolk sac angiogenesis were apparent by E9.0 and obvious at E9.5. There was an apparent block to 5 remodeling at the capillary plexus stage, for both arterial vessels as revealed by β -galactosidase staining and venous vessels in the anterior region of the sac as revealed by PECAM staining. Thus, disruption of the *EphrinB2* ligand gene caused both a non-autonomous defect in EphB4 receptor-10 expressing venous cells, and an autonomous defect in the arteries themselves.

This defect was accompanied by a failure of intercalating bi-directional growth of arteries and veins across the antero-posterior extent of the yolk sac, so that 15 an interface between *EphrinB2*-expressing and non-expressing zones at the midpoint of the sac was apparent. (However, small patches of *lacZ* expression were occasionally visible within the anterior venous plexus, suggesting that some arterial endothelial cells may have become incorporated into 20 venous capillaries.) These observations imply a close relationship between the remodeling of the capillary plexus into larger vessels and the intercalating growth of these vessels. The large β -galactosidase⁺ vitelline arteries as well as vitelline veins present at the point of entry to the 25 yolk sac of the embryo-derived vasculature appeared unperturbed in the mutant, however. This is consistent with the observation that the mutation does not affect formation of the primary trunk vasculature. It also argues that the yolk sac phenotype is due to a disruption of intrinsic 30 angiogenesis and is not secondary to a failure of ingrowth of embryo-derived vessels.

Histological staining (hematoxylin) of sectioned yolk sacs revealed an accumulation of elongated support cells (mesenchymal cells or pericytes) in close association with

the endothelial vessels at E10 and E10.5. In mutant yolk sacs, these support cells appeared more rounded, suggesting a defect in their differentiation. Moreover, in contrast to heterozygous yolk sacs, where vessels of different diameters 5 began to appear at E9.5 and vessel diameter increased through E10.5, capillary diameter appeared relatively uniform and did not increase with age in the mutants. At E10.5, arteries appear dilated, as if fusion of vessels occurred without encapsulation by support cells. The mutant 10 capillaries also failed to delaminate from the basal endodermal layer.

Example 6: Absence of internal carotid arterial branches and defective angiogenesis of venous capillaries in the head of mutant embryos

Sub D7 Similar to the yolk sac phenotype, the capillary bed of the head appeared dilated in the mutant, and apparently arrested at the primary plexus stage. Staining for α -galactosidase revealed that the anterior-most branches of the internal carotid artery failed to develop in the mutant. 20 Unlike the case in the yolk sac, therefore, the malformed capillary beds must be entirely of venous origin. However the anterior branches of the anterior cardinal vein formed although they were slightly dilated. Taken together, these data indicate that in the head, venous angiogenesis is 25 blocked if the normal interaction with arterial capillaries is prevented. The angiogenic defects observed in the head and yolk sac are unlikely to be secondary consequences of heart defects (see below), since they are observed starting at E9.0 and the embryonic blood circulation appears normal 30 until E9.5.

Example 7: EphrinB2-dependent signaling between endocardial cells is required for myocardial trabeculae formation

Examination of ligand and receptor expression in wild-type hearts revealed expression in the atrium of both

5 EphrinB2 (as detected by lacZ staining) and EphB4 (as detected by *in situ* hybridization). Expression of both ligand and receptor was also detected in the ventricle in the endocardial cells lining the trabecular extensions of the myocardium. Double-labeling experiments suggested that

10 the ligand and receptor are expressed by distinct but partially overlapping cell populations, although the resolution of the method does not permit us to distinguish whether this overlap reflects co-expression by the same cells, or a close association of different cells. In any

15 case, expression of EphrinB2 and EphB4 does not define complementary arterial (ventricular) and venous (atrial) compartments of the heart, unlike the extra-cardiac vasculature.

Heart defects commenced at E9.5 and were apparent in

20 mutant embryos at E10 both morphologically and by wholemount PECAM-1 staining. Sections revealed an absence of myocardial trabecular extensions, although strands of EphrinB2-expressing endocardial cells were still visible. Thus, mutation of the ligand-encoding gene caused a non-

25 autonomous defect in myocardial cells, similar to the effect of a mutation in the *neuregulin-1* gene. (Meyer, D. and Birchmeier, C, *Nature* 378:386-390 (1995)) Paradoxically, however, in this case the EphB4 receptor is expressed not on myocardial cells, as is the case for the *neuregulin-1*

30 receptors erbB2 and erbB4 (Lee *et al.*, *Nature* 378:394-398 (1995); Gassmann, *et al.*, *Nature* 378:390-394 (1995), but rather on endocardial cells. Expression of any of the other receptors for Ephrin B family ligands (Eph B1, B2, B3 and A4) was detected in this tissue. This suggests that in the

heart, ligand-receptor interactions among endothelial cells may in turn affect interactions with smooth muscle cells.

Example 8: Ephrin B2 is required for vascularization of the neural tube

In *EphrinB2*^{tlacZ}/*EphrinB2*^{tlacZ} embryos capillary ingrowth into the neural tube failed to occur. Instead, *EphrinB2*-expressing endothelial cells remained associated with the exterior surface of the developing spinal cord. Comparison of α -galactosidase to pan-endothelial PECAM-1 and EphB4 expression provided no evidence of a separate, venous capillary network expressing EphB4 in the CNS at this early stage (E9-E10). Rather, expression of a different *EphrinB2* receptor, Eph B2, was seen in the neural tube as previously reported Henkemeyer, et al., *Oncogene* 9:1001-1014 (1994), where no gross morphological or patterning defects were detectable. In this case, therefore, the mutation does not appear to cause a non-autonomous phenotype in receptor-expressing cells, rather only an autonomous effect on ligand-expressing cells.

卷之三

EQUIVALENTS

While this invention has been particularly shown and described with references to preferred embodiments thereof, it will be understood by those skilled in the art that 5 various changes in form and details may be made therein without departing from the spirit and scope of the invention as defined by the appended claims. Those skilled in the art will recognize or be able to ascertain using no more than routine experimentation, many equivalents to the specific 10 embodiments of the invention described specifically herein. Such equivalents are intended to be encompassed in the scope of the claims.
